# 1 Introduction

The project is a system that provides the ability to define and share touristic pedestrian routes. It allows area exploration by utilizing user made routes as virtual tour guides to other users. Essentially a user of the Social Routing Application is be able to:

- Create any Route that is possible to represent on a map.
- Search user made routes and see them drawn on a map.
- Perform any chosen Route while being tracked by location in a live fashion.
- View his own or other user's profile.
- Rate routes based on his experience when undergoing such route.

## Use case

In the context of the application, a route is a path from point A to point B, that goes through user selected sub paths that might either have relevance or simply provide the fastest way to the next point of interest of that route.

An example of events when using the application might be:

A user at his hotel decides he wants to go sightseeing for an hour and check the surrounding area by foot.

- The user starts the application and searches for a route specifying either his location or a desired one.
- The search parameter Cultural is chosen as a route category.
- The application suggests the first five routes available that match the user parameters.
- The user selects one of the suggested routes and is shown the route on a map.
- The user chooses to begin the route and receives directions in real time on a map that he has to follow to undergo such route until it is done.
- The user finishes the route and evaluates it.

This document describes the project's decisions and reasons behind them. It starts with the description of the global system architecture where a general system view is described. After that each component of the system is explained in greater detail. It finalizes with tests made to the system and the conclusion.

## 2 System Architecture

The system architecture organizes the system's necessities into manageable blocks as shown in figure 2.1. It is essentially divided into two major components, the Social Routing Client Application [10] and the Social Routing Service with a third one being the external services.

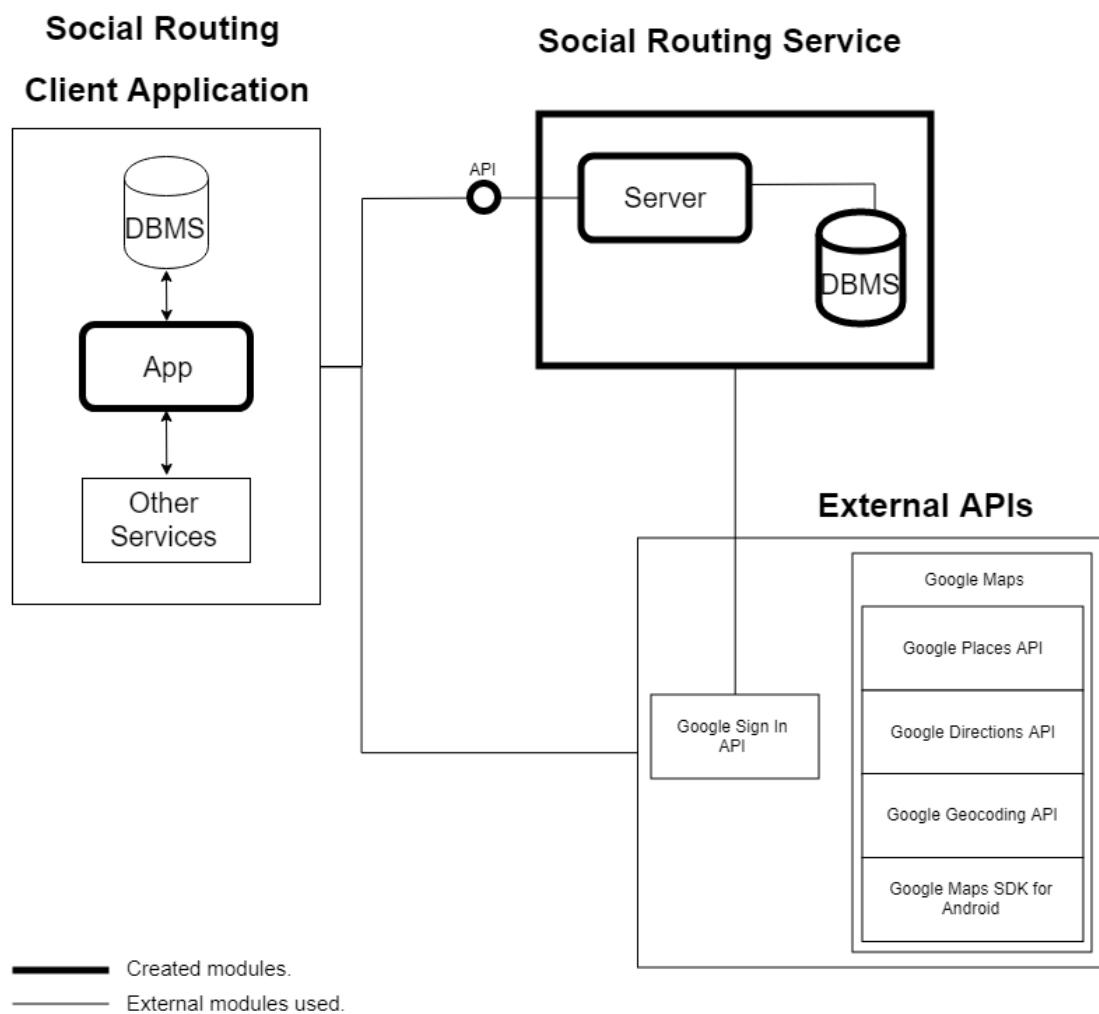

Figure 2.1: System structure.

The Social Routing Service is subdivided into two components, the Server and the Database Management System[12]. The Server exposes its functionality through an HTTP[13] API[6] (Social Routing API [32]) and as such, receives requests from a client, processes the received request and responds accordingly. The Database Management System is used to store the server's data, over which the necessary calculations are made. The Social Routing Service uses only one external API, Google Sign In[18], which is used to help with user authentication. to it.

The role of the Social Routing Client Application is to provide an interface to Android [2] devices which the user can interact with, to expose the project idea and essentially to demonstrate the Social Routing Service functionalities to the client. This component communicates with the Social Routing Service and external services when required, through the HTTP protocol. The external services are APIs provided by the Google Maps platform [17] to retrieve information such as the user profile from google accounts and content that helps managing the the Google maps, like locations, places and routes.

To authenticate a user in the system every component has a role, and because of it the general logic of authentication is part of the system's description. The 2.2 describes the authentication logic in the project's scope.

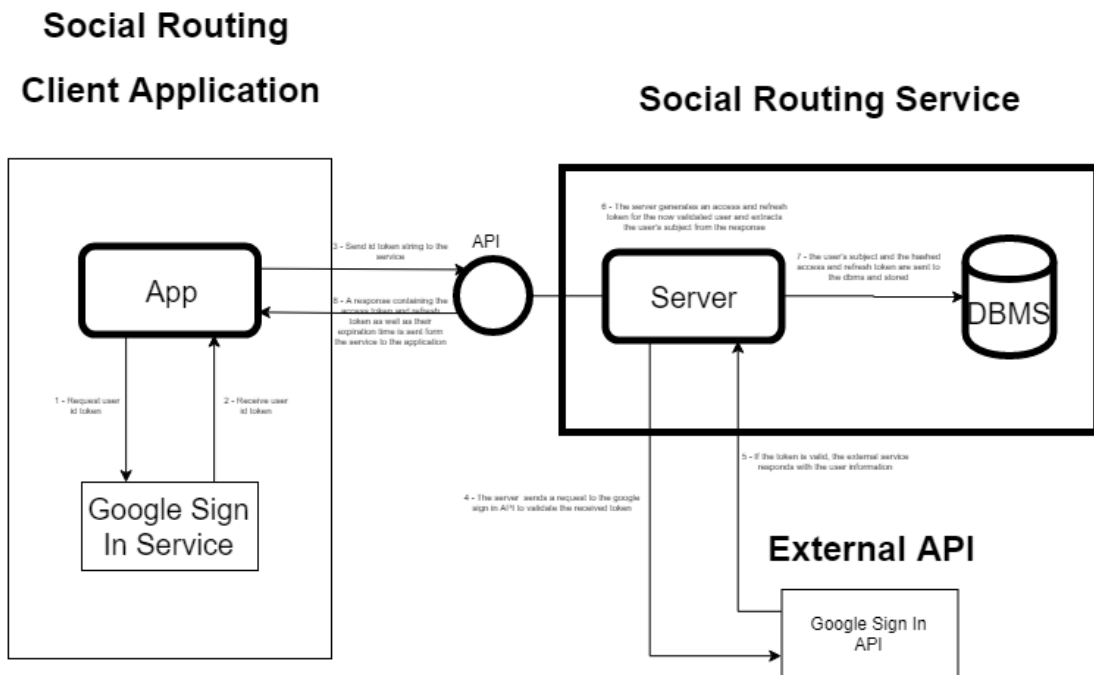

Figure 2.2: Authentication diagram.

### 3 Social Routing Service

The Social Routing Service (SRS) is comprised of three major components, a PostgreSQL based database to store user related information, a spring application to process data and an API to expose it's functionality. This logic is represented in the figure 3.1. Beyond the mentioned components it also uses the external API Google Sign In to aid with the user authentication process.

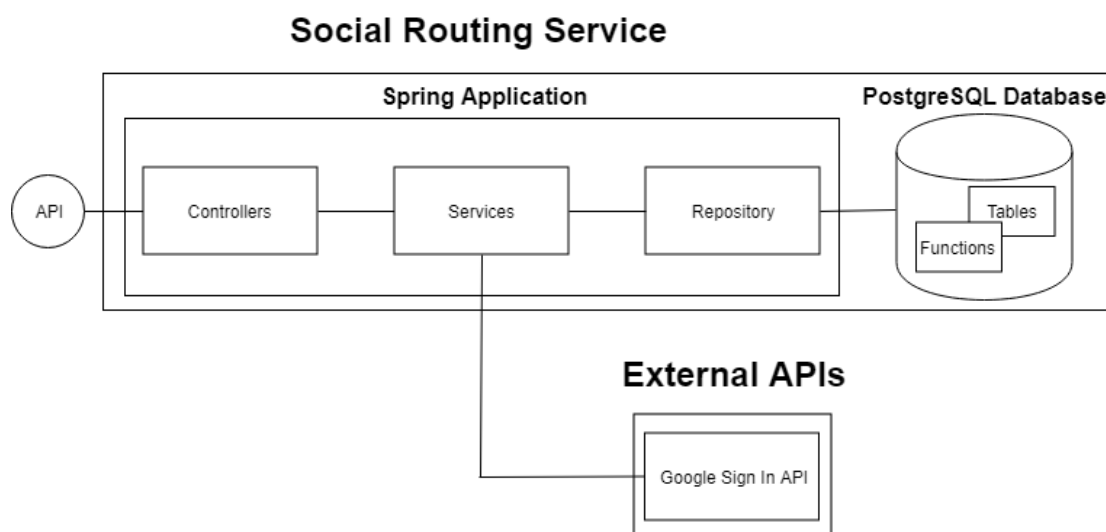

Figure 3.1: Social Routing Service architecture.

The components, although separated, must communicate with each other in order for the SRS to function properly. The API is exposed by the server using the HTTP protocol. The communication with external APIs made by the server is done through the HTTPS[20] protocol.

The communication with the DBMS is made using JDBI[23], a library built on top of the JDBC[22] driver. The main idea when building the communication with the DBMS was to guarantee that a single request made to the service would use a single connection to the DBMS. For that reason, the connection is both created and closed in the controller element of the system. This way it allows that the DBMS connection is used multiple times by the same request if required.

## 3.1 Data Model

The DBMS chosen was PostgreSQL[28], using the hybrid functionality of storing valid JSON[25] directly in a table field. The decision of choosing JSON as a type to store data comes with the need of storing large sets of coordinates belonging to a single entity and this allows us to make faster and easier calculations of times and distances between routes and points rather than if a point was it's own database entity. The main concept of the project is the creation of routes in a map and their retrieval according to certain parameters. To consider distance between a user and a route a possible search parameter, the PostGIS[27] PostgreSQL extension was used as it allows both cartesian and geodesic distances calculations.

### 3.1.1 Conceptual Model

The database entity diagram is shown in figure 3.2.

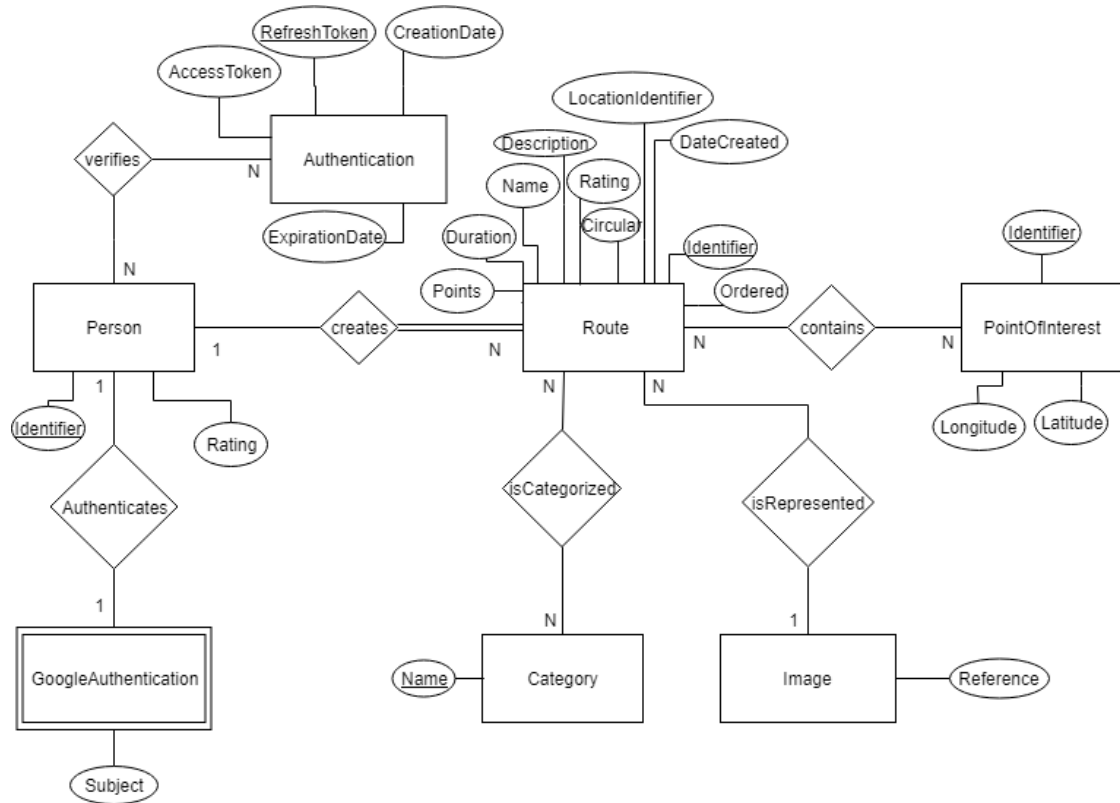

Figure 3.2: Entity Relationship Diagram.

#### Person

The entity **Person** represents a single user in the database.

## **Route**

Entity that stores every information required to represent a Route. Special consideration was taken into the making of this entity as a Route must have large sets of coordinates, representing the path that it undergoes.

## **GoogleAuthentication**

Google Authentication is the entity that stores the user unique identifier in the Google platform, the subject. In the future there will be multiple entities with different forms of authentication, hence the name GoogleAuthentication of the entity. It provides scalability to further augment the authentication process, which can be done with a new entity FacebookAuthentication for example.

## **Authentication**

This entity is used to store authentication metadata regarding each database user. The tokens have an expiration time, and because of it their creation date is required as well as their expiration date.

## **Category**

The category entity defines a route in a broader sense. It is used to filter the amount of routes being searched by a user. It can be one of the several: Sea, Sports, Cultural, amongst others. Each route must be assigned at least one category.

## **PointOfInterest**

A route might contain geographic points of interest along its path, this is the entity that represents them.

## **Image**

When a route is created it must be associated with a cover image.

### **3.1.2 Physical Model**

The physical model can be seen in a full in the database documentation[36], the following subsections discuss some of the table fields considered important.

## **Person**

The table person has only two fields, the identifier of the person, generated by the database and the person's rating. A user can have multiple entries on the Authentication table to enable multiple device registration, but only a single Google Authentication entry as the google account is unique.

## **Route**

The route table has amongst others, a field called points. This field is of type JSON, and is used to store sets of geographic coordinates. The field is a JSON array of point objects and has the following structure:

```
[
  {
    "latitude" : double ,
    "longitude": double
  },
  ...
]
```

This structure allows the mapping of multiple points to a single route.

## **GoogleAuthentication**

The google authentication table is used to store google account information, more specifically the subject which is primary key. Only one google account per user is allowed.

## **Authentication**

The authentication table stores the user credentials generated by the Social Routing Service. It contains the access token, the refresh token, the date of creation and the expiration date of the access token as well as the person identifier. The primary key of the table is the refresh token, as a single person can have multiple entries on this table, to allow multiple devices to be logged in while maintaining the same account.

## **Category**

The category entity characterizes a route in a broader sense. It is used to filter the amount of routes being searched by a user. It can be one of the several: Sea, Sports, Cultural, amongst others. The categories available are manually inserted to the database. Each route must be assigned at least one category.

## **PointOfInterest**

A point of interest is a pair of geographic coordinates (latitude and longitude) and it's reference to the google platform.

## **Image**

The table image contains a single field which is it's primary key, a reference. This is the image's unique identifier in the google platform.

### 3.1.3 Search Route

The SRS allows that a client searches routes that are nearby to a set of geographic coordinates (latitude and longitude). This functionality could be implemented in either the server or the DBMS, but with the PostGIS capabilities already mentioned, the later was chosen.

The search by proximity algorithm is built on two phases, the initial filtering by data received as parameter, to reduce the amount of calculations required, and the calculations on the resulting set of routes to check if they belong to a user area or not.

More specifically, when searching for routes close to a user's coordinates, the initial parameters must be the lower bound radius and the upper bound radius. These parameters build a circumference around the user's coordinates that goes from the lower radius to the upper one. With these parameters, if no routes are found in the specified radius, the radius can be increased or decreased in repeated searches without incurring in the overhead of filtering the already discarded routes.

The following example illustrates the data required to make such search: A user has the coordinates 38.755833, -9.116667 and is searching for short routes, that are sports related. With this data, first the city where the coordinates belong is found. After that, a query is made to the database to find which routes in the given coordinates city are short and sports related. This is the first phase of filtering. The second phase is to filter the retrieved routes by distance to the original coordinates. If they are inside the given radius, they are selected, if not, discarded.

To be able to calculate if a route belongs to a user given area, the user coordinates are transformed into a Geographic Object[14], then, each of the already filtered and retrieved routes is checked for distance to that geographic object. To be noted that the construction of a geographic object is necessary because the calculations being made are not made on the cartesian plane but on the spatial one. They must be made considering a spherical object to provide accurate results (in case a long distance between route points exists). Of course each route contains every geographic point in its field points, which is of type JSON. Of each of the routes the points must be extracted and converted into the same Geographic Object type. From here, using the built in function of the PostGIS extension STDistance [40], the distance between points is retrieved, if it's contained in the initially chosen radius, it's selected, otherwise it is not.

## Social Routing API

### Schema

The Social Routing API uses the HTTP protocol as a medium to communicate and all the data sent or received must be in the JSON format. The base endpoint of the API is : `http://api.sr`.

Data obtained from the API is either a single resource or a collection of resources. For example, a request made to retrieve a route will have as a response a single resource which will contain the representation of that route. If a request is made to obtain routes

by location then the response will be a collection of resources containing the several route representations. This single and collection terms when associated with a resource were decisive in the choice of how much data would be returned in either of them. A request for a collection doesn't require detailed information about each element of the collection, it needs to provide general information and a form for the API user to retrieve detailed information about a specific collection element. With this idea in mind the resource representations were divided into two types, a detailed representation for when a user requests a single resource and summary representation for each element inside a requested collection, containing only the information about that element that is necessary. Examples of both a detailed and summary representation can be found in the Schema Documentation [35].

## Authentication

The authentication has two different endpoints, one to obtain credentials to access the API and the other to refresh the already obtained credentials. To make an authenticated request to the API the user must make every request with the already obtained access token in the Authorization header of the request.

### Obtaining credentials

To obtain API credentials a POST [19] request must be made to the endpoint: `http://api.sr/auhtentication/google`, with the id token string in the body of the request:

```
{
  idTokenString : "id token string"
}
```

The request to this endpoint receives a response containing all the necessary data to make authenticated requests to the API. An example response:

```
{
  "accessToken" : "access token 1",
  "refreshToken": "refresh token 1"
}
```

### Refreshing the credentials

To refresh credentials a POST request must be made to the endpoint: `http://api.sr/auhtentication/refresh` containing in it's body the refresh token. If the refresh token is valid a response with a new access token and refresh token is generated.

### 3.1.4 Supported HTTP Methods

Due to the nature of the HTTP protocol, the API supports four different HTTP request methods [31]: GET, POST, PUT and DELETE.

#### GET

This method is used to retrieve resources from the API. The request:

```
GET http://api.sr/persons/1
```

retrieves a resource representing a person resource with the identifier 1. The response to this request would be:

```
{
  "identifier": 1,
  "rating": 4,
  "routesUrl": "http://api.sr/persons/1/routes"
}
```

#### POST

The POST HTTP method is used to create resources. It requires that the Content-Type[11]HTTP header is defined with the value application/json[7]. An example of a post request can be found in the API POST[33] documentation. A response to a POST request has an empty body and returns the location of the created resource in it's Location header. If successful the status code of a POST request response is 201.

#### PUT

The PUT method is used to replace or update a resource or a collection of resources. Like the post request it requires that the request contains the HTTP header Content-Type defined with application/json. The following request replaces the currently existing resource route with identifier 1 with the one sent in the body of the request. A successful response has the 200 OK status and an empty body. An example of a put request can be found in the API PUT[34] documentation.

#### DELETE

DELETE, as the name implies is utilized to delete a resource. The request:

```
DELETE http://api.sr/routes/1
```

deletes the route with 1 as identifier. A successful response will have the 200 OK status and an empty body.

### 3.1.5 Pagination

Requests that return a collection of resources will be paginated to a default value of 10 resources within the collection. A specific page can be requested with the query parameter page. If no page is specified then the first page is assumed by default. The request:

```
GET http://api.sr/persons/1/routes?page=1
```

The response would contain a collection of the first ten routes that a person with identifier 1 created. To obtain the next ten one would simply change the value of page to 2. If no further routes are available then a response with the status not found and error code 404 is returned.

### 3.1.6 Errors

The error responses follow the RFC standard of type problem+json[26]. An error response example:

```
{
  "type": "Social-Routing-API#unsupported-media-type\cite{unsupportedmedia",
  "title": "The requested type is not supported.",
  "status": "415",
  "detail": "The xml format is not supported."
}
```

The type field contains a link to the API documentation which further describes the type of error generated. The title describes succinctly what the error is about. The status is the corresponding HTTP status for the specific error. Detail is a more detailed message about the error encountered.

## Hypermedia

Some resources have links to other resources. Either to a parent resource or to a detailed representation of a resource within a collection. For example, a user resource has a link to their created routes, which holds a collection of routes. That same collection has a link to the profile of the person who created the routes.

## 3.2 Server

The server uses Kotlin as a programming language and the Spring framework[39]. It's role within the system is data receipt, data processing, and to respond accordingly. It is divided in three major layers, each with it's role in the Social Routing Service's system. They are the Controllers, the Services and the Repository.

The Controllers are responsible for handling the reception of an HTTP request to the service and are mapped to it's endpoints. Upon receiving a request they will use the available services to perform desired operations either over a set of received data or to generate the requested data.

The Services are responsible for processing data and communicating the the Repository layer.

The Repository layer is the only layer with direct access to the database and as such is responsible for communicating with it. The communication is made through the use of JDBI[23], a library built on top of the driver JDBC[22]. This allows less verbose code while maintaining control over SQL queries.

Besides these three major layers the server contains other important components, the Interceptor[38] and the Exception Handler[37]. There are three different implementations of the Interceptor component.

The Authentication Interceptor is responsible for user authentication before the request reaches a controller. The goal of this implementation is to avoid server overhead, resolving the authentication before the request is processed allows for a fast response if the user is incorrectly authenticated instead of continuing with the unnecessary processing of data.

The Logging Interceptor is used both before and after the request is processed to provide information regarding each request for debugging purposes.

The Media Type Interceptor is used, like the Authentication Interceptor, to avoid overhead, since if a post request is made with wrong Content-Type headers or no headers at all then the service does not support that request and can respond with an error immediately.

The Exception Handler is the component responsible for the handling of exceptions of the system. In the Spring framework there are several ways to handle exceptions, but the choice to make is to either handle the exceptions locally or globally. The handler implementation groups all the exceptions thrown by the system in a single class and produces their respective error messages. It allows for an easier work flow when treating exceptions. The global handling was chosen because most of the exceptions happen in more than one endpoint and would produce a lot of repeated code if handled locally.

As an example, the flow of a correct HTTP POST request to the routes resource that arrives on the server is the following:

- The request is intercepted by the Logging Interceptor and logs the request information.
- It is then intercepted by the Media Type Interceptor, that checks if the request data format received is supported by the service.
- The Authentication Interceptor checks the user credentials to see if the user can indeed access the service.
- The endpoint is reached in it's mapped Controller, which receives the Route information and that it maps to the correct object. In this case the Route Controller which will then call a service responsible for processing the request data.
- The service, in this case Route Service, will process the data and map it to the correct data type and make a request to the repository to store the received data.
- The repository communicates with the database, to which it sends the data in a database accepted format.
- The database stores the data and returns the identifier of the newly created Route.
- The repository receives the identifier and passes it through to the Route Service.
- The Service passes the received information to the Route Controller.
- The Route Controller builds the newly created route resource URI with the received Route identifier and maps it to the header Location of the response and returns.

### 3.3 Authentication

The nature of the project requires that user information such as user made routes is stored and because of this user authentication is required.

The service handles two main types of authentication requests, one to generate the user credentials and the other to refresh or update already existing credentials. A detailed view of the Social Routing Service and the components that interfere with the authentication process can be seen in 3.3.

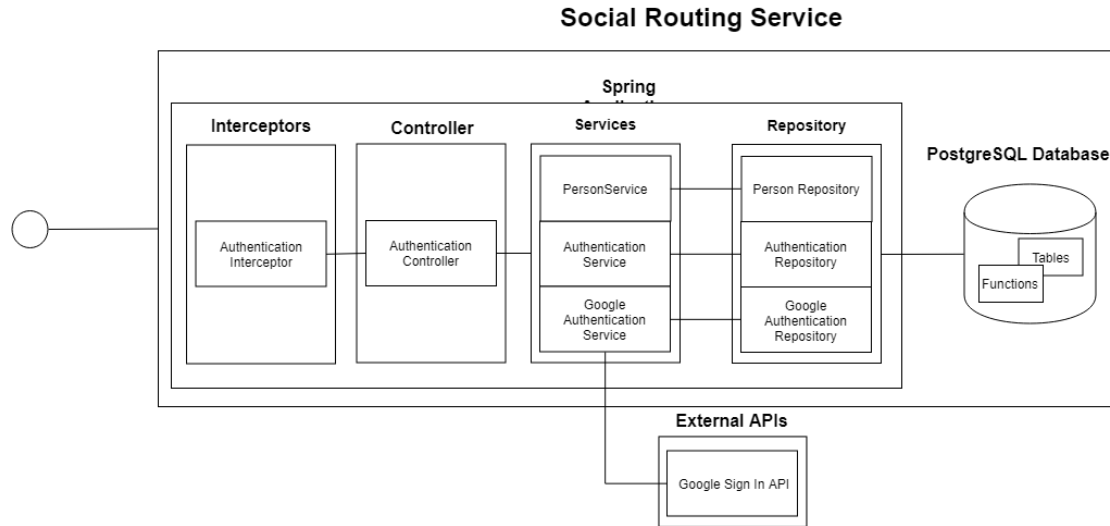

Figure 3.3: Authentication components diagram.

#### 3.3.1 Generation of Credentials

When a request is received, as mentioned in 3.1.3, it must contain the id token string of the user's google account. When the controller receives it the first step is validation of the token, for that an external API is used (Google Sign In API), that has it's usage wrapped in the `GoogleAuthenticationService`[15]. This service is responsible for all actions pertaining Google Authentication's specific processing. Once the token is validated and the sub extracted from it, the sub is checked against the database to see if any user with it is already registered, if not, the user is created. Along with user creation, the controller requests both the access token and refresh token from the `AuthenticationService`'s[9] available functionalities. The tokens are generated using Java's `SecureRandom` class[30] and hashed before being stored in the database. The access token and refresh token are sent in their original form as a response to the request maker, so that further API requests have valid credentials.

### 3.3.2 Credentials Refreshment

A valid API user will have both an access token and a refresh token to make authenticated requests to the API, but the tokens themselves have a duration of a day. For this reason if an API client makes a request to it and a day has passed since the token has been obtained then the client needs to update his credentials. To do that a request must be made using the refresh token, obtaining newly generated credentials from the service.

Apart from these two distinctions, the service client still also needs to worry about making authenticated requests, which can be made by adding a valid access token to the Authorization header of the response as detailed in section 3.1.3. Behind every request made to the service, the Authorization header is checked, to validate the user making the request. This is made in the `AuthenticationInterceptor` class [8].

## 4 Social Routing Client Application

The Social Routing Client is composed by four major components, each with it's own compromise and objective. The Activities[1] and Fragments[3] to represent the User Interface (UI) where the user can interact with the application, the View Models[5] to store and manage UI related data, a Repository that handles data operations and knows where to retrieve data from and a Remote Data Source to communicate with external components, for instance the Social Routing API or the Google Sign-In API[18]. This logic is represented in the figure 4.1.

Figure 4.1: Social Routing Client architecture.

## Activities/Fragments

The concern of this component is to provide a way for the user to interact with the application. All activities extend a BaseActivity that has a global behavior such as when the data is changed and is necessary to update the view.

Each Activity has its own :

- Design: defined by one or more layouts that contains buttons, images, input text, fragments (for instance the map fragment provided by Google), with which the user can interact.
- Behavior: when the data changes the view needs to be updated, behavior this, that is defined with either a success or error, using the ViewModel.

An example activity is the NavigationActivity where the user can navigate to all the functionalities of the application, after google authentication, like the creation of a route, search or the user profile. This activity has a left panel where you can navigate to other activities with different purposes such as route creation or the user profile. However the activity itself has the search functionality, where you can input the location name that is pretended and a button to navigate to the activity that shows the results of that search.

## View Models

Component used when the UI experiences a change. The View Model calls other components to load the data, and it can forward user requests to modify the data however it doesn't know about UI components, it is completely separated from them.

This component has a simple implementation, the application contains two View Models one for the Routes information (get, creation, update, search) and the other to the User (get, delete). It uses the repository to obtain the data and then return it in the shape of LiveData[4].

## Repository

The Repository Handles data operations, knows where to get the data from and what API calls to make when the data is updated. A repository can be considered a mediator between different data sources, such as web services.

The application has a repository specified to the Social Routing API and another to Google Maps API[16]. Each one as correspondent Web Service that uses the framework Retrofit[29], used to make a synchronous or asynchronous HTTP request to the remote webserver. The Repository obtains the data from the web server and can only have two possible request status: Failure or Success. It returns the data contained in a LiveData because when the data updates can then be observable.

The Repository specific to our API (Social Routing API) knows all the endpoints that

should make the request, depending on the objective and the functionality, like the endpoints to sign in, to get user info, routes, create a route, get all categories, update a route, amongst others.

On the other hand the other repository is used to make request to the Google Webserver (Google Maps API) about the geocode of a location and the directions to a coordinate in the map.

## Remote Data Source

Module that has the objective of communicating with external APIs which it does by executing requests to either the Social Routing API, the Google Maps API or the Google Sign-In API. The Component knows the structure of the HTTP request to the endpoints, like the parameters and meta-data necessary to obtain the required Response. After the request is done, the webserver provides the response in the Json[24] format, however the response is deserialized using the library Jackson[21], to convert it to Object. So was defined all the input model objects, to automatically deserialize the response to object.

The Client Application has the minimum API level 19 and the target API level is 28, so the Platform version is the Android 9. It uses Kotlin as the only programming language in the project which is an object oriented programming language. The goal was to improve the coding experience in a way that was practical and effectual. Kotlin is entirely compatible with Java and was specifically designed to improve existing Java models by offering solutions to API design deficiencies.

The core functionalities of the application require a map to create the routes and to show them which was done using the Google Maps API. All the functionalities of the application are provided from the Social Routing Service, except all that is related to the Google Maps. All the information is obtained from the server by doing requests to the correspondent endpoint and it is always necessary to send either the token created by the server or the Google Sign-In API tokenId, used on the user registration process. The requests that are related to location retrieval or Map UI require a specific request to the Google Maps API.

## Use Case

As an example, the user first experience flow of the application is the following:

- The user provides his google account credentials to authenticate with the application, which in its turn makes a request to the backend server.
- The user will be redirected to a navigation screen that contains a route search bar and a left panel menu with buttons to redirect to the screens of user profile and route creation.
- After the user searches routes using a location, a redirection to a new screen occurs in which a list of found routes is shown.
- Once a route is chosen and pressed upon, a new activity with a map is shown, where the route is represented and with a button to start Live Tracking.
- By choosing to start Live Tracking the user location is now showed as well as a path to reach the beginning of the chosen route.
- If the user wants to see the his profile he may go back until the navigation screen and click in the left panel and then in the User Profile button.
- In the user profile the user information (user rating, name, email and routes created) is shown.
- For creating a route, a button press in the bar menu is required.
- This action takes the user to a new screen that shows the map, a button to finish and a form, asking the location of the route that will be created.
- The user must then insert the location on which the map will zoom in.
- A click in the map will add the pressed location point to the route being created. If something wrong occurs the user can delete the last point of the route clicking the button on the top of the screen.
- When finished the user click in the button to fill the final form that contains the name, description and category of the route.

## 5 Conclusion

All the functionalities are currently done but some still need work done to be improved. On the client side both the route search functionality and Live Tracking functionalities are done, albeit in a minimalistic way, the route creation and representation functionality are fully implemented and will only change upon addition of new functionalities. User authentication, using the google account to authenticate is also completed. The Server side is close to complete lacking only (complete) error handling, finish pagination and search algorithm improvement.

The expectations to this beta version are pretty similar to the current state of the system, however some problems were found configuring the entire system. One of the first problems encountered was how a route should be defined. Several iterations were made before arriving at the current one. We avoid saying final because the definition of a route is susceptible to change when new functionalities are implemented.

While implementing the Client Application some problems were encountered when utilizing the Google Maps API, namely the API key and the service's usage. Without an account with a credit card associated we were limited to one API call per day, which was limiting our testing capabilities. This was overcome by creating a wallet (offered by the service with an initial value). The process that is required to create a route was also a problem, there are some considerations to be had due to the nature of a path: where it starts, where it ends, if it is circular, if it is doable in a determined time amongst others. This topic is intertwined with route definition, changes in the definition also change the creation.

The Service had problems initially with the connection to the Database Management System, specifically because the choice of technologies was not the appropriate one, which forced a shift to a different one. This used valuable time because two different libraries were learned (Spring Data and JDBI) and later Spring Data was discarded.

Some of the final changes might be the global optimization of the system regarding all the functionalities and the core changes might be in the route Search Algorithm that should have the best possible route suggestions, the route live tracking that should send to the user some notifications to help him go through the route and reliable system tests to ensure that everything is working properly. Small adjustments to all functionalities will occur as well to guarantee that the structure and representation are in their best possible state.
